Identification of Hic–5 as a Novel Scaffold for the MKK4/p54 JNK Pathway in the Development of Abdominal Aortic Aneurysms

Xiao-Feng Lei, PhD; Joo-ri Kim-Kaneyama, PhD; Shigeko Arita-Okubo, BSc; Stefan Offermanns, MD, PhD; Hiroyuki Itabe, PhD; Takuro Miyazaki, PhD; Akira Miyazaki, MD, PhD

Background—Although increased amounts of reactive oxygen species in the pathogenesis of abdominal aortic aneurysm (AAA) are well documented, the precise molecular mechanisms by which reactive oxygen species induce AAAs have not been fully elucidated. This study focused on the role of hydrogen peroxide–inducible clone 5 (Hic-5), which is induced by hydrogen peroxide and transforming growth factor-β, in the cellular signaling of AAA pathogenesis.

Methods and Results—Using the angiotensin II–induced AAA model in Apoe−/− mice, we showed that Apoe−/− Hic-5−/− mice were completely protected from AAA formation and aortic rupture, whereas Apoe−/− mice were not. These features were similarly observed in smooth muscle cell–specific Hic-5–deficient mice. Furthermore, angiotensin II treatment induced Hic-5 expression in a reactive oxygen species–dependent manner in aortic smooth muscle cells in the early stage of AAA development. Mechanistic studies revealed that Hic-5 interacted specifically with c-Jun N-terminal kinase p54 and its upstream regulatory molecule mitogen-activated protein kinase kinase 4 as a novel scaffold protein, resulting in the expression of membrane type 1 matrix metalloproteinase and matrix metalloproteinase 2 activation in aortic smooth muscle cells.

Conclusion—Hic-5 serves as a novel scaffold protein that specifically activates the mitogen-activated protein kinase kinase 4/p54 c-Jun N-terminal kinase pathway, thereby leading to the induction and activation of matrix metalloproteinases in smooth muscle cells and subsequent AAA formation. Our study provided a novel therapeutic option aimed at inhibiting the mitogen-activated protein kinase kinase 4–Hic-5–p54 c-Jun N-terminal kinase pathway in the vessel wall, particularly through Hic-5 inhibition, which may be used to produce more precise and effective therapies. (J Am Heart Assoc. 2014;3:e000747 doi: 10.1161/JAHA.113.000747)

Key Words: aneurysm • Hic-5 • JNK-signaling scaffold protein • smooth muscle

Abdominal aortic aneurysm (AAA) is an age-associated disease that affects approximately 5% of elderly individuals and is responsible for a significant number of deaths in Western countries.1 Oxidative stress, generated by excessive reactive oxygen species (ROS), has been shown to play causal roles in AAAs.2,3 Animal models deficient in ROS-generating enzymes, such as inducible nitric oxide synthase, NADPH oxidase-1, and p47phox, clearly demonstrated preserved aortic wall morphology and attenuated AAA development.4–6 Increased activities of matrix metalloproteinases (MMPs) play a key mechanical role in the formation of AAAs.7,8 A strong mechanistic link exists between increased ROS production and MMP activity. As has been reported recently, angiotensin II (Ang II) induces the generation of ROS in vascular smooth muscle cells (VSMCs), which triggers the activation of MMPs and vascular inflammatory responses, thereby promoting the formation of AAAs in an animal model.2,9 However, little is known about the detailed signaling pathways that regulate these processes.

Hydrogen peroxide–inducible clone 5 (Hic-5), originally identified as a gene induced by H2O2 as well as transforming growth factor-β1 (TGF-β1), has been shown to serve as a focal adhesion protein that belongs to the paxillin family.10 We recently successfully generated Hic-5–deficient mice, which were viable and fertile and had no obvious abnormalities.11

DOI: 10.1161/JAHA.113.000747
The molecular basis of Hic-5 and its implications in various pathophysiological conditions, including vascular remodeling, have already been described. However, whether Hic-5 is involved in AAA formation is unknown. In this study, we analyzed the potential role of Hic-5 in AAA formation. We found that AAA formation and rupture were almost completely prevented in Hic-5–deficient mice. Mechanistic studies showed that Hic-5 served as a novel scaffold protein to regulate c-Jun N-terminal kinase (JNK) pathway activation, which resulted in MMP expression and activation in VSMCs and the subsequent formation of AAAs.

Methods

Generation of Mice

All experiments were conducted in accordance with the protocols approved by the Institutional Committee for Animal Research of Showa University. All of the mice were bred in C56BL/6 background genotype. 

To generate the mouse model of Ang II–induced aneurysm, we used our previously described inducible SM-specific Cre recombinase with a modified estrogen receptor binding domain (CreER<sup>T2</sup>) under the control of the SM-specific SM myosin heavy chain promoter (SMMHC). The SMMHC-Cre gene is located on the Y chromosome in this mouse line, and only male offspring carried the SMMHC-Cre gene. The Hic-5<sup>F/F</sup>/SMMHC-Cre<sup>Y+</sup> mice strain was used. 

The Hic-5<sup>F/F</sup>/SMMHC-Cre<sup>Y+</sup> mice were intercrossed with a transgenic mouse line expressing inducible SM-specific Cre recombinase with a modified estrogen receptor binding domain (CreER<sup>T2</sup>) under the control of the SM-specific SM myosin heavy chain promoter (SMMHC). The Hic-5<sup>F/F</sup>/SMMHC-Cre<sup>Y+</sup> mice strain was used. 

Male Hic-5<sup>F/F</sup>/sCre<sup>Y+</sup> mice (5 to 6 weeks old) were injected with tamoxifen (1 mg/day IP) on 5 consecutive days. The day of the last tamoxifen injection was defined as day 0. The Ang II treatment was performed for 4 weeks from day 55 after the tamoxifen injection. All animals were housed under a 12-hour light/12-hour dark regimen and consumed a normal chow diet.

The Mouse Model of Ang II–Induced Aortic Aneurysm

The mouse model of Ang II–induced aneurysm formation has been previously described. Ang II was infused via the use of ALZET model 2004 osmotic pumps (ALZA Corp) at 1000 ng/kg per minute. After 4 weeks of infusion, aneurysm size was evaluated by measuring maximal abdominal aortic diameters with a digital caliper. Systolic blood pressure was measured in conscious mice by using the tail-cuff method (MK-2000; Muromachi Kikai Co). Serum total cholesterol concentrations were determined by using a cholesterol determination kit (Wako Chemicals).

Histological Analysis

After the animals were killed, their aortas were perfused with 10% phosphate-buffered formalin for 5 minutes. Whole aortas were harvested and fixed with 10% formalin for 24 hours. The aortas were cut and embedded in paraffin or OCT compound for the preparation of cross sections (5 μm). Paraffin sections were stained with hematoxylin and eosin (H&E) staining and Victoria Blue H&E staining or used for immunostaining. Frozen sections were used for immunofluorescence.

Immunohistochemistry

Formaldehyde-fixed paraffin sections and frozen sections were incubated with primary antibodies overnight at 4°C. The primary antibodies used were Hic-5 monoclonal (BD Biosciences), α-SM actin monoclonal (Sigma-Aldrich), and rat anti-mouse macrophage-monocyte specific monoclonal (AbD Serotec). As a negative control, isotype-matched antibodies were used in place of the primary antibodies. Slides were viewed with use of a microscope (IX70; Olympus) and digital camera (DP72; Olympus). Immunofluorescence images were captured and analyzed with Lumina vision software (Mitani Visual System).

Harvest of Mouse Aortic VSMCs

The preparation of mouse aortic VSMCs was performed as previously described. In brief, aortas were isolated from Hic-5<sup>F/F</sup> and Hic-5<sup>F</sup>/c mice, followed by separation of tunica media from the adventitia and endothelium. The cells were dispersed in collagenase and elastase and maintained in Dulbecco’s modified Eagle’s medium. Passage 2 to 8 VSMCs were used for experiments.

Western Blotting

VSMCs were harvested on ice-cold lysis buffer. In some experiments, VSMCs were infected with adenovirus encoding Hic-5 (Ad-hic-5/flag) or β-galactosidase (Ad-β-gal) as a control. Aortic tissue samples were crushed with a biomasher (Nippi) and lysed in lysis buffer. Equal amounts of protein were separated by 10% SDS-PAGE. Immunodetection was performed using the following primary antibodies: Hic-5; GAPDH and MMP2 (Santa Cruz Biotechnology), membrane type 1 (MT1)-MMP (Sigma-Aldrich); extracellular signal-regulated kinase (ERK), p38, mitogen-activated protein kinase kinase (MAPKK; also known as MKK) 4, MKK7, and their
phosphorylated (P) forms (P-ERK, P-p38, P-MKK4, P-MKK7, and P-JNK1/2) (Cell Signaling); and JNK1/2 (Santa Cruz Biotechnology). The densities of the bands were measured using Light-Capture and Densitograph software (AE-6962FC, CS Analyzer version 2.0; ATTO).

Gelatin Zymography and In Situ Zymography

The evaluation of MMP activities in response to Ang II was performed as described previously. To analyze the role of Hic-5 in Ang II–induced MMP activation, VSMCs were treated with Ang II (1 μmol/L) for 24 hours. Aortas from Apoe+/− and Apoe−/−Hic-5−/− mice infused with Ang II for 7 days were incubated in culture medium for 20 hours. The medium was then collected and centrifuged to remove cell debris. The conditioned medium was concentrated and electrophoresed in SDS-PAGE gels containing gelatin (Sigma-Aldrich). Gels were washed in 2.5% Triton X-100 and incubated overnight in zymography buffer (50 mmol/L Tris, pH 7.4, 10 mmol/L CaCl₂) at 37°C. Gels were subsequently stained with Coomassie brilliant blue. For in situ zymography, freshly cut frozen aortic sections (10 μm) were incubated with a fluorogenic gelatin substrate (DQ gelatin; Invitrogen) dissolved to 25 mg/mL in zymographic buffer. Proteolytic activity was detected as green fluorescence with microscopy (IX70; Olympus, Japan). Negative control zymograms were incubated in the presence of 5 mmol/L EDTA.

Immunoprecipitation

Aortic media were lysed in RIPA buffer containing a mixture of protease inhibitors and 1 mmol/L sodium vanadate for immunoprecipitation studies. Dynabeads (Invitrogen) conjugated with an antibody against Hic-5 or control mouse IgG (Santa Cruz Biotechnology) were added to the lysates (5 μg per sample) and rotated at room temperature for 60 minutes. Samples were washed with RIPA buffer 3 times and soaked in elution buffer for 10 minutes. Immunoprecipitated proteins were then processed for SDS-PAGE and Western blot analysis.

In Situ Proximity Ligation Assay

The in situ proximity ligation assay (PLA) method allows the subcellular colocalization of protein–protein interactions to be determined. Mouse VSMCs were cultured in cover glasses. After culture in serum-free medium for 24 hours, VSMCs were treated with or without Ang II for 10 minutes. VSMCs were then washed in PBS and fixed with 4% paraformaldehyde for 15 minutes. PLA assays were performed as recommended by the manufacturer (OLink Biosciences). Red fluorescent spots were then visualized with microscopy (IX70; Olympus). The negative control was performed without primary antibodies.

Electron Microscopic Observations

Immunoelectron microscopy was performed as previously described. Briefly, sections of mouse aortas were incubated overnight with primary antibodies at 4°C. After the sections were washed with PBS, 10-nm gold-labeled sheep anti-mouse IgG and 15-nm gold-labeled goat anti-rabbit IgG secondary antibodies (BBI International) were used; subsequently, sections were evaluated with Hitachi H-7600 transmission electron microscope.

Statistical Analyses

The data are presented as mean±SEM. Statistical tests including the Mann–Whitney test (for comparisons of parameters among 2 groups), Gehan-Breslow-Wilcoxon test (for survival curves), Fisher’s exact test (for aneurysm incidence), and 2-way ANOVA using the Bonferroni posttests (for comparisons of different parameters between 2 genotypes) were performed using GraphPad Prism (version 5.0 for Mac) software. P<0.05 was considered statistically significant.

Results

Hic-5 Deficiency Suppressed Ang II–Induced AAA Formation and AAA Rupture

Ang II infusion for 4 weeks induced AAA formation in Apoe−/− mice. Here, we used Apoe−/− mice and Apoe−/−Hic-5−/− mice to investigate the role of Hic-5 in the pathogenesis of Ang II–induced AAs. Ang II infusion increased systolic blood pressure in both groups to the same extent (Table). No significant difference in cholesterol levels was observed between these 2 groups after Ang II infusion (Table).

No aneurysm was detected in either group after saline infusion (Figure 1A). Ang II infusion markedly induced AASs in 87% (13/15) of Apoe−/− mice (Figure 1A and 1C), while only 11% (1/9) of Apoe−/−Hic-5−/− mice developed small AAs. We also noted that maximal aortic diameter (Figure 1B and 1D) was significantly smaller in Apoe−/−Hic-5−/− mice than in Apoe−/− mice. Interestingly, over the 4 weeks of the experiment, 40% (6/15) of the Apoe−/− mice infused with Ang II died in the first week, whereas none of the Apoe−/−Hic-5−/− mice died during the entire experiment (Figure 1E). Apoe−/− mice showed arterial rupture and massive bleeding in the abdominal cavities (Figure 1F and 1G). In Victoria Blue H&E staining, which specifically demonstrates elastic fibers in the background of H&E-stained tissues, the elastic lamina was

\(\downarrow\) No significant difference between Apoe\(^{-/-}\) and Apoe\(^{-/-}\) Hic-5\(^{-/-}\) or Apoe\(^{-/-}\) Hic-5\(^{f/f}\)/sCre\(^{Y}\) mice.

We first investigated the expression of Hic-5 in aortic tissues from normal and Ang II-infused Apoe\(^{-/-}\) mice. Consistent with our previous report, Hic-5 was highly expressed in SM cells (SMCs) in addition to endothelium (Figure 2A) but not in macrophages in the aortas of Apoe\(^{-/-}\) mice after the Ang II treatment for 7 days or 4 weeks (Figure 2B and 2C). The expression pattern of Hic-5 was similar to that of \(\alpha\)-SM actin in both normal aorta and AAA lesions, which was consistent with our previous report. Although macrophages have been reported to have a crucial role in the development of Ang II–induced AAAs, Hic-5 was not detected by immunostaining in the macrophages of AAA lesions (Figure 2B) or by Western blotting analyses in cultured macrophages (data not shown).

To obtain direct evidence for the key role of VSMC-derived Hic-5 in AAA formation, we created SM-specific Hic-5 knockout mice (SM-Hic-5 KO). We used a transgenic mouse line, which expressed in an SMC-specific manner a tamoxifen-inducible Cre recombinase under the control of the SMMHC promoter, bred to the well-established Hic-5\(^{lox/lox}\)/SMMHC-Cre\(^{+}\) (Hic-5\(^{f/f}\)/sCre\(^{Y}\)) mice (see “Methods” for details) were treated with tamoxifen as shown in Figure 3A. As a control, we used Hic-5\(^{f/f}\)/sCre\(^{Y}\) mice to which tamoxifen was not administered. The successful SMC-specific deletion of Hic-5 in the aortic media was shown by Western blotting after the tamoxifen treatment (Figure 3B). Cre expression in this mouse line has previously been shown to be specific for vascular and visceral SMCs.

We also noted that tamoxifen treatment suppressed Hic-5 expression in the colon (Figure 3B) but not in the lung. Hic-5 was expressed mainly in the endothelium and pneumocytes rather than SMCs in the mouse lung (data not shown).

By crossing male Hic-5\(^{f/f}\)/sCre\(^{Y}\) mice with female Apoe\(^{-/-}\) mice, Apoe\(^{-/-}\) Hic-5\(^{f/f}\)/sCre\(^{Y}\) mice were generated. The Ang II treatment was performed from day 55 after the tamoxifen injection (Figure 3A) using tamoxifen-injected Apoe\(^{-/-}\) mice as a control. The successful SMC-specific deletion of Hic-5 in tamoxifen-injected Apoe\(^{-/-}\) Hic-5\(^{f/f}\)/sCre\(^{Y}\) mice was confirmed with use of Western blotting assay of the aortic media after the Ang II treatment, which showed a 98% reduction in Hic-5 protein levels after the tamoxifen treatment (Figure 3D). In contrast, Hic-5 expression in the aortic media from Apoe\(^{-/-}\) mice was not affected by tamoxifen. Systolic blood pressure and total cholesterol levels were not significantly different between the 2 groups (Table). Although total cholesterol levels were decreased after the tamoxifen treatment in Apoe\(^{-/-}\) mice, as previously reported, treatment of Apoe\(^{-/-}\) mice and tamoxifen-injected Apoe\(^{-/-}\) mice with Ang II for 4 weeks induced AAA formation (13/15 and 5/7, respectively) and AAA rupture (6/15 and 3/7, respectively) to the same extent. However, in contrast to tamoxifen-injected Apoe\(^{-/-}\), a marked reduction in AAA rupture (0/8), AAA formation (1/8), and maximal aortic diameter was observed in tamoxifen-injected Apoe\(^{-/-}\) Hic-5\(^{f/f}\)/sCre\(^{Y}\) mice (Figure 3C, 3E through 3G). These results suggest that the loss of Hic-5 expression in aortic VSMCs, but not other aortic wall cells, is crucial for Ang II–induced AAA formation.

We next examined the effects of Ang II on Hic-5 expression in the aorta from Apoe\(^{-/-}\) mice and cultured aortic VSMCs. Hic-5 levels in aortic tissues were significantly enhanced in Apoe\(^{-/-}\) mice in the early stage of Ang II infusion (Figure 4A). Hic-5 expression was also increased by Ang II in a concentration-dependent manner in cultured mouse aortic VSMCs (Figure 4B). As was previously reported, Ang II increased the amount of NADPH oxidase–derived ROS in aortic VSMCs. Pretreatment with ROS scavenger N-acetyl-L-cysteine markedly reduced Ang II–induced Hic-5 expression (Figure 4B).

Hic-5 Deﬁciency Prevented Ang II–Induced MMP Expression and Activation in VSMCs

Among the MMPs, VSMC-derived MMP-2, which is cleaved by Ang II and activated by Ang II–induced Hic-5, is crucial for Ang II–induced AAA formation. Hic-5 expression was also increased by Ang II in a concentration-dependent manner in cultured mouse aortic VSMCs (Figure 4B). As was previously reported, Ang II increased the amount of NADPH oxidase–derived ROS in aortic VSMCs. Pretreatment with ROS scavenger N-acetyl-L-cysteine markedly reduced Ang II–induced Hic-5 expression (Figure 4B).
Hic-5 deficiency blocked Ang II–induced AAA formation and AAA rupture in vivo. Apoe<sup>−/−</sup> and Apoe<sup>−/−</sup>Hic-5<sup>−/−</sup> mice were treated with Ang II or saline for 4 weeks. for 7 days in Apoe−/− mice markedly increased the expression of proMMP2 and activated MMP2 in the aortic media (Figure 5A). The induction of these 2 MMP2 proteins by Ang II infusion was significantly weaker in Apoe−/−Hic-5−/− mice than in Apoe−/− mice (Figure 5A and 5B). We next focused on MT1-MMP, a major activator of proMMP2. Basal expression of MT1-MMP was negligible in the aortic media from both Apoe−/− and Apoe−/−Hic-5−/− mice. The Ang II treatment increased MT1-MMP protein expression in both groups; however, the induction of MT1-MMP was significantly attenuated in Apoe−/−Hic-5−/− mice (Figure 5A and 5C). Gelatin zymography of the aortas from Apoe−/− showed an increase in proMMP2 and activated MMP2. In contrast, Ang II–treated aortas from Apoe−/−Hic-5−/− mice showed markedly reduced MMP2 expression and activation (Figure 5D). We obtained a similar result by in situ zymography, which showed that Ang II infusion markedly increased MMP activity in the medial layers of Apoe−/− mice but not in Apoe−/−Hic-5−/− mice (Figure 5E). MMP activity was negligible in both Apoe−/− and Apoe−/−Hic-5−/− mice after saline infusion (Figure 5E). We also observed that the Ang II treatment induced the expression of MT1-MMP and MMP2 in cultured VSMCs isolated from Hic-5+/+ mice, whereas VSMCs from Hic-5−/− mice did not exhibit such an upregulation (Figure 5F and 5G). As shown with gelatin zymography, the secretion and activation of MMP2 in the culture media were lower in Hic-5−/− VSMCs than in Hic-5+/+ VSMCs (Figure 5F, lower panel). In contrast to VSMCs, macrophages did not express Hic-5. As expected, no significant difference in MMP9 production was observed for macrophages from Hic-5+/+ and Hic-5−/− mice (data not shown).

### Hic-5 Regulated Phosphorylation of the JNK Pathway in VSMCs

We next analyzed the mechanism for decreases in MMP secretion and activation by Hic-5 deficiency. Although the enhanced production of ROS and associated vascular inflammation are known to accelerate Ang II–induced MMP induction and subsequent AAA development and progression,2,5,26 we found that Hic-5 deficiency in Apoe−/− mice did not affect Ang II–induced ROS production or the secretion of proinflammatory cytokines and chemokines in cultured VSMCs and isolated aortas (data not shown).

The JNK pathway was previously shown to upregulate the expression of MMPs including MMP2 and MT1-MMP.17,27 We next investigated whether Hic-5 was required for JNK activation by phosphorylation. VSMCs from Hic-5+/+ and Hic-5−/− mice were treated with Ang II at the indicated times, and the phosphorylation of JNK was analyzed (Figure 6A). We used anisomycin, a potent stimulator of JNK, as a positive control.28 Figure 5A showed no significant differences between Hic-5+/+ and Hic-5−/− VSMCs in the phosphorylation of ERK1/2 and p38 after the Ang II treatment. However, Ang II–induced phosphorylation of JNK was markedly lower in Hic-5−/− VSMCs than in Hic-5+/+ VSMCs, particularly in phosphorylation of p54 JNK, in which...
Figure 5. Ang II–induced MMP expression and activation were inhibited in the Hic-5+/− mouse aorta and cultured VSMCs. Representative immunoblots for proMMP2, MMP2, and MT1-MMP in the aortic media after Ang II infusion for 7 days (A) and immunoblots for MMP2 and MT1-MMP in cultured VSMCs after the Ang II treatment for 48 hours (F, upper 2 panels) in the indicated genotypes. (B, C, and G) Densitometric analyses of immunoblots for proMMP2, MMP2, and MT1-MMP after normalization with GAPDH. Data are expressed as means±SEM of 3 independent experiments. *P<0.01 significantly different from Apoe−/− mice (B and C) or Hic-5+/− VSMCs (G). Gelatin zymography of conditioned medium from the whole aorta organ culture (D) or cultured VSMCs (F, lowest panel) in the indicated genotypes. E, Aortas from Apoe−/− and Apoe−/− Hic-5+/− mice infused with saline or Ang II for 7 days were analyzed by in situ zymography for gelatinase activity. Active MMPs are indicated by the green color. Scale bars, 50 μm. H, VBHE staining of aortas from Apoe−/− and Apoe−/− Hic-5+/− mice 4 weeks after Ang II infusion. The arrows indicate degradation of the elastic lamina in Apoe−/− mice. AAA indicates abdominal aortic aneurysm; Ang II, angiotensin II; Hic-5, hydrogen peroxide–inducible clone 5; MMPs indicates matrix metalloproteinases; VBHE, Victoria Blue hematoxylin & eosin; VSMCs, vascular smooth muscle cells.
phosphorylation was almost completely suppressed even under anisomycin stimulation (Figure 6A and 6B). In vivo, the Ang II treatment of Apoe−/− mice for 7 days significantly induced the phosphorylation of JNK, as shown by Western blotting assay of the aortic media. In contrast, a marked reduction in the phosphorylation of JNK after Ang II infusion was observed in Apoe−/− Hic-5−/− mice (Figure 6C). We next restored Hic-5 expression in Hic-5−/− VSMCs through adenovirus-mediated gene transfer (Ad-hic-5/flag), using the β-galactosidase gene (Ad-β-gal) as a control. Compared with control gene, exogenous Hic-5 (flag-tagged) expression in Hic-5−/− VSMCs efficiently restored basal and Ang II–induced phosphorylation of JNK, especially p54 JNK (Figure 6D). We next examined whether Hic-5 served as a component of the JNK pathway. JNK protein kinases are activated by phosphorylation by MKK4 and MKK7, which are well known as adjacent upstream kinases of JNK.29,30 We found that Hic-5 deficiency hardly affected the phosphorylation of MKK7 (data not shown). However, the phosphorylation of MKK4 was significantly higher in Hic-5−/− VSMCs than in Hic-5+/+/− VSMCs, even at basal levels (Figure 6E).

**Hic-5 Is Associated Directly With MKK4 and JNK**

The specificity of signal transduction depends on specific protein–protein interactions. Scaffold proteins, including the JNK interacting protein group bind to MKK4 and/or MKK7, in addition to JNK, and coordinate signal transduction in the JNK pathway.30,31 As described previously, Hic-5 serves as a scaffold of integrin signaling through interactions with multiple signaling molecules.12 Because Hic-5 deficiency led to the decreased phosphorylation of p54 JNK and increased phosphorylation of MKK4, we reasoned that Hic-5 may serve as a scaffold protein between MKK4 and p54 JNK. To test this possibility, we performed immunoprecipitation experiments using an Hic-5–specific antibody and aortic tissue lysate from Hic-5−/− mice. The results showed that the Hic-5 antibody pulled down JNK, especially p54 JNK and MKK4, but not MKK7, p38, or ERK together with Hic-5 (Figure 7A). Using the specific antibody of JNK1 and JNK2, we found that JNK2 is primarily composed of the p54 JNK isoform in cultured mouse VSMCs (data not shown).

To further validate the association of Hic-5 with p54 JNK or MKK4 in Hic-5−/− VSMCs, we performed in situ proximity ligation assays, which identify the subcellular localization of interacting endogenous proteins within approximately 40 nm at single molecule resolution.32 A fluorescent signal by this method (red dots) indicated the association of Hic-5 with p54 JNK or MKK4. Clear red spots were detected with the Hic-5 antibody in combination with the JNK2 antibody or MKK4 antibody in Hic-5−/− VSMCs, whereas only background staining was obtained with the Hic-5 antibody in combination with control IgG (Figure 7B). These results indicate that Hic-5 colocalized with p54 JNK and MKK4 within 40 nm in VSMCs. The colocalization of these molecules was further demonstrated by using an immunoelectron microscopic method in aortas from Hic-5−/− mice (Figure 7C). We next analyzed the interaction of Hic-5 with P-JNK or P-MKK4 in cultured Hic-5−/− VSMCs using PLA assays. More red fluorescent dots were detected with the Hic-5 antibody in combination with the P-JNK antibody or P-MKK4 antibody in VSMCs after Ang II treatment than in those detected with the control (untreated with Ang II) (Figure 7D), suggesting that Hic-5 also contributes to the association of P-JNK and P-MKK4 in VSMCs. Together, these results suggest that Hic-5 serves as a scaffold selective for p54 JNK and MKK4 in VSMCs and contributes to the activation of p54 JNK by binding to both MKK4 and p54 JNK (Figure 7E).

**Discussion**

We showed that Ang II–induced ROS promoted the expression of Hic-5 in VSMCs, which subsequently accelerated the phosphorylation of JNK, especially p54 JNK. Mechanistically, Hic-5 can bind to both p54 JNK and its upstream regulatory molecule, MKK4. Suppression of the p54 JNK pathway by Hic-5 loss resulted in the limited secretion of proMMP2 and MMP2 and expression of MT1-MMP, which led to protection from elastin degradation and subsequent AAA formation and rupture (Figure 8). This study not only identified Hic-5 as a downstream molecule of ROS, which promotes AAA formation, but also suggested that Hic-5 can serve as a specific scaffold between MKK4 and p54 JNK in VSMCs.

Although numerous studies have clearly demonstrated that ROS play an important role in the development of aneurysms, no strong therapeutic strategy currently exists for the clinical benefits of antioxidant administration. One potential reason for this could be the crucial role of ROS in mediating the transduction of intracellular signals that are also important for regulating both VSMC and vascular functions.33,34 Our findings not only demonstrated that Hic-5, as a downstream molecule of ROS in the transduction of intracellular signals, regulates AAA development but also that its absence did not affect ROS production or normal function in mice. In addition, Hic-5 specifically binds to p54 JNK and its upstream molecule, MKK4, and plays an essential role in the phosphorylation of p54 JNK in VSMCs. Although the inhibition of JNKs has been considered as a potential therapeutic target for aneurysms,17 JNKs have been shown to play critical roles in adult tissue homeostasis. In fact, the knockout of both Jnk1 and Jnk2 genes in mice was shown to be an embryonic lethal mutation.35 Thus, targeting JNKs themselves may be limited to be used as a mainstream treatment approach. Therefore, the exact JNK isoform (JNK1...
Figure 6. Hic-5 deficiency inhibited the phosphorylation of c-Jun N-terminal kinase (JNK) in VSMCs. A, Representative immunoblots of VSMCs are shown for MAP kinases (ERK, p38, and JNK) and for their phosphorylated forms (P-ERK, P-p38, and P-p54/p46 JNK, respectively) in the indicated genotypes after the Ang II (10^{-7} mol/L) or anisomycin (AN; 20 μg/mL) treatment. B, Quantitative analyses of P-p54/p46 JNK are shown after normalization with GAPDH. C, Phosphorylation of p54/p46 JNK was detected using mouse aortas from Ang II–infused Apoe−/− mice for 7 days. Quantitative analyses of P-p54/p46 JNK are shown in the lower panel. D, Adenovirus-mediated expression of flag-tagged Hic-5 (Ad-Hic-5/flag) in Hic-5−/− VSMCs induced the phosphorylation of p54/p46 JNK. Hic-5−/− VSMCs were infected with Ad-Hic-5/flag or the adenovirus-mediated β-galactosidase gene (Ad-β-gal) as a control. After 12 hours of infection, the expression of P-JNK and Hic-5 with or without the Ang II treatment was analyzed by immunoblots. E, Enhanced phosphorylation of MKK4 in Hic-5−/− VSMCs. The levels of MKK4 phosphorylation induced by Ang II were detected at each of the indicated times. AN was used as a positive control. All results are means±SEM of 3 independent experiments. *P<0.01, #P<0.05 significantly different from Hic-5+/+ VSMCs (B and E) or Apoe−/− mice (C) or infected with Ad-β-gal gene (D). AAA indicates abdominal aortic aneurysm; Ang II, angiotensin II; Hic-5, hydrogen peroxide–inducible clone 5; JNK, Jun N-terminal kinase; MKK, mitogen-activated protein kinase; VSMCs, vascular smooth muscle cells.
Figure 7. Hic-5 interacted with p54 JNK and MKK4 in VSMCs. Coimmunoprecipitation of p54 JNK and MKK4 with the Hic-5 antibody in the mouse aorta. Immunoblots for p54/p46 JNK, MKK4, ERK1/2, p38, MKK7, and Hic-5 in the total lysates of the mouse aorta or that after immunoprecipitation with the Hic-5–specific antibody or nonimmune mouse IgG as a negative control. IP, immunoprecipitation. B, Interaction of endogenous Hic-5 and p54 JNK or MKK4 in cultured Hic-5+/+ VSMCs. PLA was carried out to detect the proximal location of Hic-5 and p54 JNK or that of Hic-5 and MKK4 (shown as red dots) as described in “Methods.” All samples were stained with DAPI (blue) to visualize nuclei. C, Immunogold electron microscopy of Hic-5+/+ mouse aortas was performed. Co-localization of Hic-5 with p54 JNK or that with MKK4 in mouse aortic SMCs was detected using secondary antibodies conjugated with larger (15-nm) gold colloids for Hic-5 (arrowheads) and smaller (10-nm) gold colloids for p54 JNK or MKK4 (arrows), respectively. D, Interaction of Hic-5 with P-JNK or that with P-MKK4 in cultured Hic-5+/+ VSMCs with or without the Ang II treatment as demonstrated by the PLA method. E, Schematic diagram summarizing the interaction of Hic-5 and p54 JNK or MKK4 in VSMCs. Red circles represent phosphorylation. Arrows indicate signal transduction for p54 JNK phosphorylation after the Ang II treatment. The red X-mark represents inhibited signal transduction by Hic-5 deficiency. AAA indicates abdominal aortic aneurysm; Ang II, angiotensin II; Hic-5, hydrogen peroxide–inducible clone 5; JNK, Jun N-terminal kinase; MKK, mitogen-activated protein kinase; PLA, proximity ligation assay.
or JNK2) is required to be identified in aneurysm formation. We found that JNK2 is primarily composed of the p54 JNK isoform in cultured mouse VSMCs. In addition, Jnk2 deficiency in mouse VSMCs markedly inhibited the secretion of MMP2. All these suggest that Hic-5–targeted therapy may be more specific for the treatment of aneurysms with minimum side effects.

Paxillin, a member of paxillin family proteins together with Hic-5, has extensive homology with Hic-5 and is known to provide an efficient scaffold for the ERK module. In the present study, we demonstrated that Hic-5 served as a scaffold for the p54 JNK module. These results raise the possibility that each paxillin family protein may behave as a respective scaffold for one of the MAPK modules.

We also found that Hic-5 expressed in VSMCs, rather than other types of cells, was essential for the development of AAAs. A couple of molecules expressed in VSMCs have been proposed to initiate AAA development by promoting the secretion of MMP2 and inflammatory cell recruitment in aneurysm formation in mice and humans. These studies strongly support our findings that VSMC-derived Hic-5 played a key role in AAA development by promoting the secretion of proMMP2 and MT1-MMP and activation of MMP2. AAA indicates abdominal aortic aneurysm; Ang II, angiotensin II; Hic-5, hydrogen peroxide–inducible clone 5; JNK, Jun N-terminal kinase; MMP, matrix metalloproteinase; MKK, mitogen-activated protein kinase; ROS, reactive oxygen species.

Figure 8. Ang II–induced AAA formation via Hic-5 in mice. Ang II binds to its receptors and induces the production of ROS in VSMCs. Ang II–induced ROS promote the expression of Hic-5 in VSMCs and Hic-5 serves as a specific scaffold between JNK p54 and its upstream molecule, MKK4, which contributes to the transmission of the activated signal from MKK4 to JNKp54. The loss of Hic-5 suppresses the JNK p54 pathway and results in the limited expression of proMMP2 and MT1-MMP and activation of MMP2. AAA indicates abdominal aortic aneurysm; Ang II, angiotensin II; Hic-5, hydrogen peroxide–inducible clone 5; JNK, Jun N-terminal kinase; MMP, matrix metalloproteinase; MKK, mitogen-activated protein kinase; ROS, reactive oxygen species.
The current study demonstrated that Hic-5 deficiency resulted in the effective suppression of AAAs in an animal model. Hic-5–targeted therapy may provide a novel therapeutic option for the treatment of AAAs in the future.
